## Abstract

*In open and heterogeneous environments, where an unpredictable number of applications compete for a limited amount of resources, executions can be affected by also unpredictable delays, which may not even be bounded. Since many of these applications have timeliness requirements, they can only be implemented if they are able to adapt to the existing conditions. Adaptation can be done by several ways, taking into account many different factors, but an obvious factor of success is knowing what they have to adapt to. In this paper we present a novel approach, called Dependable QoS adaptation, which can only be achieved if the environment is accurately and reliably observed.*

*Dependable QoS adaptation is based on the Timely Computing Base (TCB) model. The TCB model is a partial synchrony model that adequately characterizes environments of uncertain synchrony and allows, at the same time, the specification and verification of timeliness requirements. We introduce the coverage stability property and show that adaptive applications can use the TCB to dependably adapt and enjoy this property. We describe the characteristics and the interface of a QoS coverage service and discuss its implementation details.*

## 1 Introduction

An increasing number of applications with timeliness or real-time requirements is being used in open, unpredictable or unreliable environments, like the internet. This is the case of multimedia applications, e-commerce or transaction based applications and applications for remote process control. For a systems' architect this may appear to be a contra-

diction, since it is well known that no real-time guarantees can be provided using intrinsically asynchronous platforms or environments. What happens in practice is that many of these applications are simply best-effort applications, or they are designed artificially assuming a synchronous system model. In the latter, the apparent guaranteed (synchronous) behavior is only achievable until the first occurrence of a *timing failure*.

Any systematic approach to the problem of implementing timeliness requirements in environments with unpredictable behavior has to take into account the effects of timing failures on the correctness of applications. However, this is not what happens with most of the known system models. For instance, in asynchronous, or time-free [16] systems, there is not even a notion of time and in synchronous systems the fault model includes crash and omission failures, but no timing failures. The timed asynchronous system model [11] allows the definition of timed services and “knows” that timing or performance failures can occur. But its basic asynchronous nature does not allow timing failures to be detected within known time bounds. So their effects can only be partially handled.

The lack of a generic model able to deal with the partial synchrony problem in a systematic way was one of the reasons that motivated our work around the definition of a new model, which we called the **Timely Computing Base (TCB)** model [23]. It assumes that systems, however asynchronous they may be, and whatever their scale, can rely on services provided by a special module, the TCB, which is timely, that is, synchronous. Under the TCB framework we define different classes of applications according to the properties that they enjoy, and we explain how to handle the effects of timing failures, with the help of TCB services, for each of these application classes (or combinations thereof).

In this paper we concentrate on the particular effect of *decreased coverage* resulting from timing failures, and show that there is a class of QoS adaptive applications, to which we refer as *time-elastic* applications, that may benefit from the TCB to avoid the decreased coverage problem. An important aspect of our work is that adaptation to environment changes relies on rigorous observations and mathe-

This work was partially supported by the EC, through project IST-2000-26031 (CORTEX), and by the FCT, through the Large-Scale Informatic Systems Laboratory (LASIGE) and projects Praxis/P/EEI/12160/1998 (MICRA) and Praxis/P/EEI/14187/1998 (DEAR-COTS).

mathematical analysis, which allows to dependably adapt the QoS (expressed as timing variables) to maintain the coverage of timeliness assumptions. We describe the QoS coverage service as an entity that can indeed be used by applications to dependably adapt.

The rest of this paper is organized as follows. Section 2 presents a brief overview of related work. Then, in section 3 we briefly present the key aspects of the TCB model. The problem of dependable adaptation is discussed in section 4, focusing on the role of the TCB in the global system architecture. Section 5 presents the QoS coverage service and in section 6 we discuss a few implementation issues. Finally, in section 7 we present our conclusions.

## 2 Related Work

The provision of quality of service (QoS) guarantees in open environments, such as the internet, is currently an active field of research. In fact, although there is a lot of work dealing with the problem of QoS provision in environments where resources are known and can be controlled [25, 21, 27, 17], no systematic solution has been proposed for environments where there is no knowledge about the amount of available resources. As we know, the Timely Computing Base (TCB) model is the only system model that characterizes these kind of unpredictable environments in a generic way, and is thus adequate to derive solutions for applications with QoS needs.

Most of the works that deal with QoS provision assume that resource reservation is possible. They address several facets of the problem and propose very diverse solutions. For instance, they propose to use benefit functions specified by the application as a way to optimize resource management [10], they describe middleware architectures to deal with heterogeneous environments [21], they propose control-based solutions [18] or they use resource brokers to manage system resources [27]. A comprehensive survey about end-to-end QoS architectures can be found in [4]. The IntServ [6] and DiffServ [5] architectures were proposed to specifically address the problem of handling QoS requirements and differentiated service guarantees in the Internet. Detailed discussions about multimedia applications over the Internet can be found in [14] and [26].

Unlike the majority of the work dealing with QoS provision, we are concerned with environments where resource reservation and QoS enforcement may not be possible. Obviously, not all applications can be implemented on these environments. They need to be *adaptive* or more particularly *time-elastic*, that is, they must be able to adapt their timing expectations to the actual conditions of the environment, possibly sacrificing the quality of other (non time-related) parameters. The success of an adaptive system has to do essentially with two factors: 1) the monitoring framework, which dictates the accuracy of the observations that

drive adaptation and 2) the adaptation framework, which determines how the adaptation will be realized.

Monitoring of local resources and processes is widely used [19, 17], but it does not provide a global view of the environment. Some works propose adaptation based on network monitoring and on information exchange among hosts (using specific protocols like RTP [7] or estimating delays [8]) but they do not reason in terms of the *confidence about the observations*, which is essential for dependable adaptation. In contrast, we focus on providing a global view of the environment (consistent to all participating entities) and on ensuring the correctness of that view.

Relatively to adaptation strategies, we mention the work in [1], that proposes adaptation among a fixed number of accepted QoS levels, and the work in [18], that uses control theory to enhance adaptation decisions and fuzzy logic to map adaptation values into application-specific control actions. However, since they have no *dependability* concerns relative to the adaptation, neither they reason in terms of a *generic model of partial synchrony* for the distributed system, we believe our work can complement them. These dependability concerns appear on the AQuA architecture, which provides adaptation mechanisms to respond to system faults and to maintain certain (dependability related) QoS levels [12]. But our dependability concerns are related with the adaptation mechanism itself, and not particularly with application dependability requirements.

The study of partial synchrony models has been the subject of some previous work, which have also addressed the problem of QoS adaptation. Cristian and Fetzer have proposed a methodology based on the timed-asynchronous model [11] to design adaptive real-time applications [15]. The quasi-synchronous model [22], developed by one of the present authors, has provided the framework to address the problem of achieving group communication in the presence of timing failures [3]. These works were in general precursors of the TCB model [24], which provides a more generic framework to address asymmetries (both in space and time) of the system synchrony and is therefore adequate to handle a vast range of problems.

## 3 Timely Computing

The Timely Computing Base model provides the framework for the work presented in this paper. However, due to space limitations, this paper just introduces the services and interface provided by a TCB module. All detailed explanations about these and other issues concerning the TCB can be found in other documents, namely in [23] and [24].

A system with a Timely Computing Base is divided into two well-defined parts: a *payload* and a *control* part. The generic or *payload* part prefigures what is normally 'the system' in homogeneous architectures. It exists over a payload network and is where applications run and communicate. In

particular, all middleware services dedicated to QoS provisioning, monitoring or management are constructed in the payload part of the system. The *control* part is made of local TCB modules, interconnected by some form of medium, the *control* network. The payload part can have any degree of synchronism, and the control part (the TCB) is assumed to be a synchronous component. A discussion about TCB implementation issues can be found in [9].

A TCB can be turned into an oracle providing time-related services to applications or middleware components. To accomplish this, a set of minimal services has to be defined, as well as a payload-to-TCB interface.

In order to keep the TCB simple, the services defined are only those essential to satisfy a wide range of applications with timeliness requirements. Therefore, the TCB provides a **Duration Measurement** service with the ability to measure distributed durations with bounded accuracy; a **Timing Failure Detection** service able to completely and accurately detect timing failures; and a **Timely Execution** service with the ability to execute well-defined functions in bounded time.

Beside defining essential services to be provided by the TCB, it is very important to provide a programming interface to allow potentially asynchronous applications to dialogue with a synchronous component. One of the most important problems is that the latency of service invocation, as well as the latency of service replies, may not be bounded. So it is not possible to relate (in a time line) events occurring in one side with events occurring in the other. The interface summarized in Table 1 (with a slightly more versatile `waitInfo()` function than the one presented in [24]) makes a bridge between a synchronous environment and a potentially asynchronous one. A description of the several functions and some examples of how to use them are presented in [24].

## 4 Dependable QoS Adaptation

Given the TCB model with its services and interfaces, which we consider the essential ones to address timeliness issues in unpredictable environments, this section analyzes the implications of using this model to construct QoS architectures.

Quality of Service can have different meanings that depend essentially on the application. This is why the definition of a completely generic model for specifying QoS needs is perhaps an impossible task: it is usually necessary to use mapping mechanisms to translate user level QoS requirements into system level ones. In the present work we assume that it is possible to define mapping mechanisms, so that QoS requirements of different applications can be specified in terms of timing variables, which are the variables of interest in the TCB model.

---

### Duration Measurement

```
timestamp ← getTimeStamp ()
id ← startMeasurement (start_ts)
end_ts,duration ← stopMeasurement (id)
```

### Timely Execution

```
end_ts ← exec (start_ts, wait, exec_dur, f)
```

### Timing Failure Detection

```
id ← startLocal (start_ts, spec, handler)
end_ts,duration,faulty ← endLocal(id)
id ← send (send_ts, spec, handler)
id,deliv_ts ← receive ()
id,dur1,faulty1 ... durn,faultyn ← waitInfo()
```

---

**Table 1. Summary of the API.**

The TCB model provides a generic framework to deal with synchronism problems and to provide certain safety and liveness properties in the time domain to applications. In this sense, there is a potential for this model to be used as a base model for the development of some application classes. Adaptable applications with QoS requirements is one of those classes.

Typically, QoS adaptable applications are realized on top of a QoS framework. This framework is defined by a compound of QoS mechanisms which altogether characterize its ability to deal with application QoS requirements. There are three basic categories of QoS mechanisms: QoS provision, QoS control and QoS management mechanisms. If we want to use the TCB as a basic model to serve the design of some end-to-end QoS architecture, we must investigate the benefits that it might bring for the implementation of these QoS mechanisms. In particular, and since the TCB model provides a set of services to applications, we must find answers for the following questions: *Which QoS mechanisms can be improved by using TCB services? How can TCB services be used to improve QoS mechanisms?* The rest of the section will essentially focus on the discussion of these questions.

### 4.1 QoS Mechanisms under the TCB Framework

Before all, recall that the TCB does not restrict the properties of the payload part of the system, which allows for any QoS architecture to be implemented in a TCB based system. In fact, we stress that a TCB is just a small component that, mostly because of its small size and simplicity, can be constructed with more synchronous properties (or can be more dependably synchronous) than the rest of the system. Therefore, simply imagine that a TCB can be plugged into any existing system and be used as an oracle that provides a few basic services. The question is whether these services can be used **to improve** the existing QoS mechanisms. Let us first take a look on these mechanisms, closely following the systematization presented in [4]

The first category of QoS mechanisms, QoS provision, allows applications to use low level services, such as communication services, and to specify desired levels of QoS. QoS provision includes the following: a) QoS mapping – to translate application level notation to system level specifications; b) Admission testing – to verify that there exist enough available resources to admit the requested QoS level; c) End-to-end reservation – to reserve resources and prevent resource outage during execution.

The second category consists of QoS control mechanisms, which serve to regulate and control the way in which resources are used and shared by the several flows (traffic or execution flows) during run-time. They include several mechanisms, namely a) Flow shapping – to regulate usage according to some formal representation (for instance, a statistical one); b) Flow scheduling – to manage the several flows in an integrated way; c) Flow policing – to verify that the contract is being adhered to by applications; d) Flow control – to guarantee resource availability, either using open loop schemes (with advanced resource reservation) or closed loop schemes (with flow adaptation based on feed-back information); e) Flow synchronization – to account for precise interactions (e.g. multimedia interactions) of different flows.

Finally, the QoS management category includes the following mechanisms: a) QoS monitoring – to observe QoS levels achieved by lower layers; b) QoS maintenance – to perform fine adaptation of resource usage to maintain QoS levels; c) QoS degradation – to deliver QoS indication to applications when QoS cannot be sustained; d) QoS availability – to allow applications to specify bounds for QoS parameters; e) QoS scalability – which comprises QoS filtering, to allow the manipulation of (traffic) flows, and QoS adaptation, to scale flows at the end system in order to respond to fluctuations in end-to-end QoS.

Now we must recall that TCB services can be used, in a general sense, to help applications observe their timeliness (using the duration measurement service), execute short real-time operations (with the timely execution service) or timely detect timing failures and react upon their detection within given time bounds. We must therefore look for QoS mechanisms that rely directly or indirectly on time, which are the ones that might be improved using these services.

Of the QoS provision mechanisms, QoS mapping and end-to-end reservation only perform logical operations and do not need timeliness informations to achieve their goals. Clearly, they are not eligible mechanisms for possible improvements. On the other hand, admission testing mechanisms need to compare available resources with requested ones, and so may possibly use the TCB to have the knowledge of available resources, measured in terms of timeliness. Relatively to QoS control mechanisms, the one that most clearly can use a TCB, in particular its duration mea-

surement service, is the closed loop flow control mechanism. The basic idea is to use the information about distributed durations (relative to end-to-end transmission of data) to derive conclusions about the correct control actions to take. Finally, the QoS management mechanisms that deal with observing the behavior of the environment (or lower level services) can also use information about distributed durations to measure the QoS level (in terms of timeliness) that is being provided in a given moment.

The fundamental conclusion is that a TCB can essentially be used to improve the mechanisms that need information about the environment. This is clearly the case of mechanisms such as the flow control or the QoS monitoring, but can also be the case of other mechanisms, such as the QoS maintenance, which by using the output of a possibly improved monitoring can also employ finer grain techniques to achieve better results.

## 4.2 Improving QoS Mechanisms

We have just seen, at least intuitively, that a TCB can eventually be useful to construct or improve any QoS mechanism that needs information about the environment. Since this information is crucial, among other things, to take correct adaptation decisions, we argue that by using a framework which explicitly addresses the unpredictable nature of the environment in terms of timeliness, it is possible to adapt applications in a dependable manner, based on the timely observation of the environment.

To demonstrate our point of view, and having in mind that timeliness is the fundamental property in this context, we take a constructive approach that consists in analyzing why systems fail in the presence of uncertain timeliness, and deriving sufficient conditions to solve the problems encountered, based on the behavior of applications and on the properties of the TCB.

### 4.2.1 Effects of Timing Failures

We assume that an application is a computation in general and that any application is defined by a set of safety and timeliness properties  $\mathcal{P}_A$ . In the absence of timing failures, the system executes correctly. When timing failures occur, it is generally assumed that the effect is **unexpected delay**. However, we observe two additional effects, which produce different pathologies in the system, by the way they affect high-level system properties: **decreased coverage** and **contamination**. We define and discuss below the effects that are relevant for the current work. The effect of contamination is discussed in detail in [23].

#### Unexpected Delay

The immediate effect of timing failures is unexpected **delay**, defined as the violation of a timeliness property. That

can sometimes be accepted, if applications are prepared to work correctly under increased delay expectations (e.g. mission-critical or soft real-time systems).

### Uncoverage

When we make assumptions about the prevention of timing failures, we have in mind a certain coverage, which is the correspondence between system timeliness assumptions and what the environment can guarantee. We define **assumed coverage**  $P_{\mathcal{P}}$  of a property  $\mathcal{P}$  as the assumed probability of the property holding over an interval of reference. This coverage is necessarily very high for hard real-time systems, and maybe somewhat relaxed for any other real-time system, like mission-critical or soft real-time systems. However, in an environment with uncertain timeliness, the actual coverage varies during system life. Each time the environment conditions degrade to states worse than assumed, the coverage incrementally decreases, that is, the probability of timing failure increases. On the other hand, if the coverage is better than assumed, we are not taking full advantage from what the environment offers. This is a generic problem for any class of system relying on the assumption/coverage binomial[20]: if coverage of failure mode assumptions does not stay stable, a fault-tolerant design based on those assumptions will be impaired, because dependability properties, such as reliability, may be violated, or one does not take full advantage of the system. A sufficient condition for that not to happen, expressed by the *Coverage Stability* property, consists in ensuring that coverage stays close to the assumed value, over an interval of mission.

In [23] we have already presented formal proofs to show that the TCB can help applications to secure coverage stability despite the uncertainty of the environment. In this paper we deal with more practical aspects, in particular with the concrete applicability of the coverage stability property.

#### 4.2.2 Enforcing Coverage Stability

The definition of coverage stability for an application (instead of for a single property) simply consists in the expression of coverage stability for all timeliness properties defined within the application. But not all applications can benefit from this property.

A class that can indeed benefit is what we define as the **Time-Elastic Class** ( $\mathcal{T}\epsilon$ ) [23]. In practical terms,  $\mathcal{T}\epsilon$  applications are those whose bounds can be increased or decreased dynamically, such as QoS-driven applications. As already mentioned, provided that correct mappings are used to express application specific QoS requirements as timeliness requirements, it is possible to include these applications in the  $\mathcal{T}\epsilon$  class and possibly enforce their coverage stability.

Coverage stability is a useful property in the presence of uncertain timeliness. It means that an application has

the guarantee that its timeliness properties will hold during execution with a constant probability. The trade-off is that they must be time-elastic, which means that they must allow run-time adaptation of their timing parameters.

To explain how can a  $\mathcal{T}\epsilon$  application achieve coverage stability under certain conditions, we must reason in terms of the services provided by the TCB and of what can be done with them. In this case, the relevant service is the duration measurement service that may provide the necessary information to construct histograms of the distribution of durations and thus gathering evidence about coverage.

Note that a timeliness property implies that a given action has always to be performed within certain time bounds. Note also that the TCB is capable of observing those executions and measure their duration. Therefore, provided that there is a minimum number  $n_0$  of *observed durations*,  $T$ , representing the *specified duration bound*,  $\mathcal{T}$  (derived from the timeliness property), it is possible to build a discrete probability distribution function *pdf* that represents the actual distribution of the timing variable with an error  $p_{dev0}$ [13]. This error depends on the measurement error introduced by the TCB and on the error introduced by the method used to build the *pdf*. With the *pdf* one can determine the probability  $P = pdf(T)$ , such that being  $p$  the actual probability of  $T$ ,  $|p - P| \leq p_{dev0}$

**Figure 1. Example variation of distribution  $pdf(T)$  with the changing environment**

In systems of uncertain timeliness, the *pdf* of a duration varies with time. Therefore, if two distinct intervals of observation are considered, what can be observed is a shift of the baseline *pdf*, as depicted in Figure 1, by curves A and B. Note that at this point we are not assuming any particular distribution, and so the curves depicted in the figure merely represent any two possible *pdf*s. Although it is enough to know that  $p_{dev}$  remains bounded, one wishes to keep the error  $p_{dev}$  small in order to predict the probability of any  $T$  accurately, even with periods of timeliness instability. To achieve this goal it is necessary to periodically rebuild the *pdf* that represents the actual distribution. One can take the previous *pdf*,  $pdf_{i-1}(T)$ , or at least a part of that history (the most recent subset of values used to compute

$pdf_{i-1}(\mathcal{T})$ , and the immediately subsequent  $n$  observed durations, and compute a new  $pdf_i(\mathcal{T})$  that reflects more accurately the current system state and forces  $p_{dev}$  to remain bounded and small.

It may not be practical to recompute a new  $pdf$  after every observed duration since this may require too many computational resources without considerable benefits. However, if the value of  $n$  is set too high and if the environment presents large variations, the accuracy of  $pdf(\mathcal{T})$  can degrade and the error  $p_{dev}$  will have to be higher. The adequate value of  $n$ , as well as the history size, depends on the behavior of the environment, and cannot be assigned an optimal value by default. What may eventually be done is the implementation of additional mechanisms to detect or learn particular behaviors and adjust the critical values accordingly to them (see section 6).

Having described the general principle that allows a  $pdf$  to be constructed with the help of a TCB service, we still have to discuss how can this  $pdf$  be used to enforce the coverage stability property of a Time-Elastic application.

The basic idea is simple and relies on the assumption that QoS requirements may be specified in terms of  $\langle bound, coverage \rangle$  pairs. This means that applications are constructed assuming that each time bound holds with a certain coverage. When the environment degrades, the only way in which it is possible to maintain the coverage is to assume a different bound. This is where the availability of a  $pdf$  becomes useful, in particular for Time-Elastic applications which are able to change the bounds dynamically. It allows to directly determine the new bound that has to be used in order to maintain the coverage. In the example of figure 1, when the environment changes and the new  $pdf B$  is obtained, the application maintains the degree of coverage by adapting the bound from  $T_A$  to  $T_B$ . Note that these remarks are also true when the environment gets faster: the bound should get back to its lower value as soon as possible.

A pertinent question that could be made at this point is about the entity responsible for building the  $pdf$ : it could be the TCB itself, or the application, or a middleware layer specifically designed for that purpose. We introduce the QoS coverage service as the logic entity in the system responsible for handling the coverage related issues. This service is presented in the next section.

## 5 The QoS Coverage Service

In a general sense, the QoS coverage service can be described as providing to applications the ability of dependably decide how to adapt time bounds in order to maintain a constant coverage level. Figure 2 illustrates the overall aspect of a system with QoS oriented services and a TCB extended with a QoS coverage service.

Applications are layered on top of the system, which provides a set of services through dedicated interfaces. We dis-

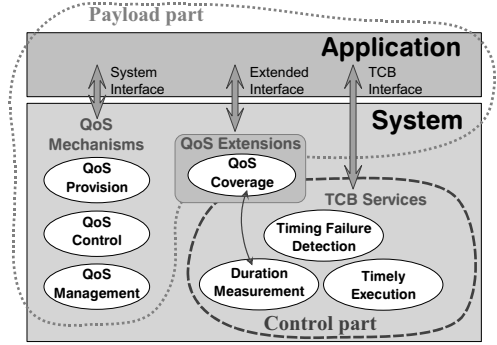

Figure 2. QoS extensions for the TCB.

tinguish three interfaces: the basic system interface, which provides access to all system services, including those related with QoS provision, control and management; the TCB interface that we mentioned in section 3; and the QoS coverage service interface, which is presented below. The payload part of the system includes everything except the TCB, which constitutes the control part of the system. As we will see, the QoS coverage service can reside in any of these two parts.

### 5.1 Service Interface

We have designed an interface for the QoS coverage service that being as simple as possible yet allows the fundamental objective to be achieved. Since this objective consists in maintain the coverage of a given timeliness property, the service has obviously to know, at least, the *bound* that must be observed and its respective desired *coverage*. In the interface functions presented in Table 2 these parameters are represented, respectively, by *bound* and *cov*. Unchanged API portions are printed in gray.

---

#### QoS Coverage

```
id ← monDistr (bnd, cov, dev, c_id, hdlr)
id ← monLocal (bnd, cov, dev, f_id, hdlr)
new_bound ← waitChange (id)
```

#### Timing Failure Detection (modified functions)

```
id ← send (c_id, send_ts, spec, handler)
id, deliv_ts ← receive (c_id)
id, dur1, faulty1 ... durn, faultyn ← waitInfo (c_id)
```

#### Duration Measurement (modified functions)

```
id ← startMeasurement (start_ts, f_id)
```

---

Table 2. Extended and modified API.

In the framework that we have defined so far, it is possible to identify two kinds of bounds. In fact, the nature of the bounds associated to actions executed locally is different from the bounds that are imposed to actions exe-

cuted among distributed nodes. For instance, this difference is quite explicit in the way durations are measured by the TCB. Because of that we have explicitly defined two different functions to request a QoS coverage service: `monDistr` is used to monitor the coverage of distributed durations and `monLocal` is used for local durations.

The duration of a distributed action always includes the delay for transmitting a message. Therefore, distributed durations can be observed as a result from messages sent through some communication channel using the modified `send` function presented in above table. The identifier of the channel, `c_id`, is necessary for the coverage service to associate a given  $\langle bound, coverage \rangle$  pair to messages transmitted through that channel. This `c_id` parameter was omitted on purpose in Table 1, but is now presented for completeness reasons. Other irrelevant parameters (for the service) are still omitted.

Similarly to distributed durations, which are associated to communication channels, local durations are associated to the execution of specific functions or parts of the code. Therefore, when requesting the QoS coverage service to monitor the coverage of a local action it is necessary to provide some identification of that action. This is done through the `f_id` identifier. Naturally, this identifier has also to be used when requesting the measurement of durations, so that these measurements can be associated to specific actions (and their respective time bounds).

For the QoS coverage service to work properly it is necessary that it knows when to inform the application that a bound needs to be adapted. It would be possible to let the service provide information whenever a new *pdf* was built, independently of the variation degree. But in the case of applications that define QoS levels and are able to adapt among these levels, this would cause unnecessary performance degradation because for small variations nothing would be done (yet an indication would be delivered to the application). To prevent this situation, both interface functions contain the `dev` parameter. It is used to indicate the deviation relative to the current bound that triggers the delivery of a QoS change indication to the application. With this parameter it is possible to configure the hysteresis of the triggering of the indications.

The last parameter, `hdlr`, can be used to provide a handler for a function that should be executed whenever a QoS change is detected. The utility of providing a handler is highly determined by the timeliness properties that are enjoyed by the QoS coverage service, but this is discussed below. On return, both monitoring functions provide an identifier, `id`, for the observed duration.

Note that independently of whether an handler is provided or not, the service always sends an indication to the application. In this interface we assume that the application is responsible for consuming and processing all indications sent by the QoS coverage service, using for that the `wait`-

Change function call. This function returns the most recent information concerning the duration identified by `id`, that is, it returns the bound that should be used in order to keep the desired coverage.

## 5.2 Service Operation

The service collects information relative to durations, builds the *pdf*, determines if it is necessary to inform the application of any considerable change and, finally, executes the appropriate actions.

Gathering information about distributed durations is done using the `waitInfo` function. Durations of local actions are explicitly observed using the modified duration measurement API function. The service keeps track of a certain amount of observed durations for each channel (`c_id`) and function (`f_id`). How the *pdf* is actually built depends on the particular implementation and on some assumptions about the environment. Therefore, this is discussed in section 6. Having some representation of the *pdf*, the current (the last reported) bound and the maximum allowed deviation, the service can easily determine if the deviation has been exceeded whenever a new *pdf* is built. If so, the new bound is recorded and reported to the application. If an handler has been specified it will be executed in the context of the QoS coverage service (whichever context this is). Whether the handler is timely executed or not depends on the timeliness properties of the service.

## 5.3 Timeliness Issues

The QoS coverage service has been so far defined as a service laying between the application and the TCB. But the consequences of implementing it in the *control* part of the system (inside the TCB) or in the *payload* part are quite different and relevant.

If the QoS coverage service is implemented as an additional TCB service, then it will obviously benefit from the fact that the TCB is a synchronous component. Every operation will be executed within known time bounds, in particular all those that are necessary for the detection of QoS changes. This means that QoS change handlers will be timely executed allowing timely reactions to QoS changes. We say that a service with these characteristics allows for **real-time, dependable adaptation**. The trade-off for having this real-time behavior is that more complexity is being added to the TCB, increasing the probability of timeliness violations within the TCB itself, and making the TCB a “less synchronous” component than it was before. To decide whether it is worth implementing the QoS coverage service inside the TCB depends on the application and on the relative benefits that it could obtain by timely adapting to QoS changes.

If implemented in the payload part of the system, the QoS coverage service will behave according to the properties of the payload. This means that nothing can be assumed with respect to its timeliness. However, since the information that is used to build the *pdf* is still obtained using TCB services, it is possible to have certain guarantees about the (logical) correctness of the results obtained using this information. For instance, it is possible to ensure that given an interval of observation only the information relative to this interval is used to construct the correspondent *pdf*. It is also possible to ensure that all components of a distributed application have the same view of the environment. This is because the TCB delivers exactly the same information about distributed durations to all participants to which this information is relevant. The result is that applications can dependably (but possibly not timely) make decisions based on that information. The service allows for **dependable adaptation** in response to changing conditions of the environment.

We have seen that it is possible to specify QoS adaptation handlers when issuing requests to the QoS coverage service. However, the kind and complexity of the operations that can be done by these handlers depends on the location of the QoS coverage service. If the service is inside the TCB, it will only allow simple operations to be executed in order to preserve the timeliness of the TCB. There is a TCB admission control layer that verifies the feasibility of the request. When the request is accepted the handler executes in the context of the TCB, benefiting from its synchrony properties. The practical implications of having two different execution contexts, the application and the TCB one, depend on the concrete implementation. It is possible to employ specific mechanisms to share parts of these contexts and still preserve the temporal integrity of the TCB.

#### 5.4 Extending the Interface

As already stated, we followed the principle of simplicity when proposing the interface for the QoS coverage service. Now we describe an important extension that can be done in order to make the service more flexible. We first recall the reader that the QoS coverage service was devised with the main objective of keeping the coverage close to the assumed value, with obvious repercussions in the proposed interface. We also recall that we have considered a particular class of applications, the  $\mathcal{T}_\epsilon$  class, containing applications with the ability to dynamically adapt their time bounds. However, we could as well have considered another class of applications, a coverage-elastic class ( $\mathcal{C}_\epsilon$ ), which includes applications that are able to withstand with variations of the assumed coverage values, keeping constant time bounds. These applications do not have to enjoy the coverage stability property. Instead, with the help of an extended QoS coverage service they can possibly enjoy a *Coverage*

*Awareness* property, that is, the ability to know at a given moment the coverage value associated to some bound. Note that they still have to be constructed assuming that each time bound holds with a certain coverage, which means that QoS is still specified in terms of  $\langle bound, coverage \rangle$  pairs. With coverage awareness these applications can employ specific adaptation procedures to handle coverage variations. For instance, they can take actions as simple as reporting the fact to the user or as complex as launching new application replicas in response to coverage degradation periods.

To accommodate this coverage-elastic class of applications, in addition to the time-elastic class, the QoS coverage service interface has to be slightly extended. The idea is to have a service that operates in one of two modes: with constant bounds or with constant coverage values. Therefore, the interface must allow for an operation mode to be specified and must be able to interpret the deviation parameter *dev* accordingly. On the other hand, depending on the selected mode, the *waitChange* function must be able to return either a new bound or a new coverage value.

## 6 Implementation Issues

The implementation of the QoS coverage service encompasses several issues, which can be discussed individually according to their specific functionalities. In this section we discuss some of these issues, in particular those related with the construction of the *pdf*, which we believe to be more relevant for the reader.

From a practical point of view, to implement a QoS coverage service it is necessary to decide which concrete algorithms and values will be used. For instance, since a *pdf* is built using a certain number of observed durations it is necessary to decide which number will this be.

We propose a method to build *pdfs* and detect QoS changes that relies on the following assumptions:

**Probabilistic behavior** – We are observing the duration of actions executed in the payload part of the system. Generically, the payload part of the system can be of any synchronism, which means that it might be synchronous, but also completely asynchronous. Consequently, there is nothing that formally limits the time it takes for actions to be executed. However, we know that when the environment is stable the execution time of specific actions usually follows some probabilistic distribution. Therefore, arbitrary behaviours can be disregarded. Nevertheless, since the execution conditions may vary, a certain probabilistic behaviour can be suddenly affected and may be transformed into a different probabilistic behaviour. This is why we assume that durations can follow any *probabilistic distribution*, and that it is not necessary to know which distribution this is.

**Recognition abilities** – The ideal situation would be to know the exact probability distribution associated to a certain duration. We know that this distribution varies and that it depends, among other factors, on the application behaviour and on the background execution context. Therefore, it would eventually be possible to apply additional run-time mechanisms in order to *recognize* at a given moment the probabilistic distribution more closely suited to the observed durations. However, we assume that we do not have enough computational power to do that during the execution.

**Regular execution** – We have mentioned that coverage should remain stable over an interval of mission. The idea is to provide a service that is well dimensioned for those intervals. We assume that applications have a regular execution, which allows the clear identification of intervals of mission. We further assume that an interval of mission contains a sufficient number of observable actions, required to construct a *pdf*. Coverage assumptions cannot be guaranteed to hold for sporadic actions.

Since we assume that the probabilistic distribution of durations is unknown, we will show that it is possible to determine  $\langle \text{bound}, \text{coverage} \rangle$  pairs for a duration  $D$ , using only the expected value  $E(D)$  and the variance  $V(D)$  relative to that duration. Then we will describe how to compute  $E(D)$  and  $V(D)$ .

We use a known result of probability theory, the *One-sided Inequality* (for instance, see [2]), which states that for any random variable  $D$  with a finite expected value  $E(D)$  and a finite variance  $V(D)$  we can bound the probability that  $D$  is higher than some value  $t$ :

$$P(D > t) \leq \frac{V(D)}{V(D) + (t - E(D))^2}, \text{ for all } t > E(D).$$

This expression can be used to calculate an upper bound for the probability of a time bound  $t$  being violated. This also corresponds to a lower bound for the coverage of the assumed bound  $t$ . For an assumed minimum coverage  $C_{min}$ , one can find the time bound  $t$  that has to be used in order to guarantee  $C_{min}$ :

$$t = \frac{2E(D) + \sqrt{4E(D)^2 - 4(E(D)^2 + V(D) - \frac{V(D)}{1-C_{min}})}}{2}$$

Obviously, if the objective is to keep constant bounds and simply be aware of the maximum possible coverage for a given bound (see Section 5.4), the expression to use has to be:

$$C_{min} = 1 - \frac{V(D)}{V(D) + (t - E(D))^2}$$

## Estimating $E(D)$ and $V(D)$

The values of  $E(D)$  and  $V(D)$  are *estimated* using a finite number of observed durations. The idea is simply to have a set of measured durations and then obtain the **average** and the **variance** corresponding to that set. The size of the set should be determined by the typical interval of mission of the application which is using the service. Note that intuitively it may seem a better approach to use as many values as possible when estimating  $E(D)$  and  $V(D)$ , even if they are outside the interval of mission. However, since we assume that the environment (and consequently the distribution) may not remain stable, by using values observed outside the interval of mission we may just be degrading the accuracy of the estimated distribution.

## Method accuracy

The accuracy of the proposed method is influenced by three kinds of errors. In the first place, the values used to estimate  $E(D)$  and  $V(D)$  (provided by the duration measurement service) have an associated error. Although this error is not explicitly provided in the interface (the measured durations are upper bounds), it would be possible to have a duration measurement service returning  $\langle \text{measurement}, \text{error} \rangle$  pairs instead of simply  $\langle \text{measurement\_upper\_bound} \rangle$ .

In the second place, there is the error associated with the estimation of  $E(D)$  and  $V(D)$ . This error obviously depends on the number of values used to obtain the estimation, which, as we have seen, should not be arbitrarily high by including values observed outside a certain interval of mission.

Finally, when using the proposed expressions derived from the one-sided inequality, we are introducing an error that depends on the “real” distribution corresponding to the duration. Since we do not assume any particular distribution, the formulas provide pessimistic but *secure* bounds, that in any case can compromise the system safety. Note that by removing the second assumption presented above (recognition abilities), it would become possible to consider specific distributions for the probabilistic behaviour of durations (e.g. exponential or normal) and avoid this last source of errors.

## 7 Conclusions

We have presented a new approach for QoS adaptation, developed in the context of the Timely Computing Base (TCB) model. We addressed the problem of providing an adequate framework and programming infrastructure to applications with QoS requirements (specifically expressed in terms of timeliness properties), running in unpredictable environments.

We introduced an innovative analysis of the effect of timing failures on application correctness. Besides the obvious effect of delay, we identified a long-term effect, of decreased coverage of assumptions, and an instantaneous effect, of contamination of other properties. Even when delays are allowed, any of these effects can lead to undesirable behavior of a system. We addressed from a practical perspective the effect of decreased coverage, and showed that there is a class of applications, the time-elastic class, which, with the help of the TCB, can dependably adapt and enjoy the property of coverage stability. We presented the QoS coverage service and discussed its synchrony properties. In particular, we compared the properties of a TCB based and a payload based QoS coverage service. We also discussed possible modifications to the interface in order to address other classes of applications as, for instance, the coverage-elastic class. Finally, a few important issues relative to the concrete operation of the QoS coverage service have also been discussed.

As future work we intend to extend our RT-Linux TCB [9] with the ideas presented in this paper. The results of this implementation will be reported in another paper.
